1 Introduction

This report has been prepared by Subacoustech Environmental Ltd for HaskoningDHV UK Ltd. and presents the underwater noise modelling results for impact piling and other noise sources relating to the construction and lifecycle of the proposed East Anglia TWO (EA2) and East Anglia ONE North (EA1N) offshore wind farm projects.

1.1 EA2 and EA1N Offshore Wind Farm overview

EA2 and EA1N are proposed offshore wind farms in development in the North Sea off the coast of Suffolk. EA2 is located approximately 31 km from the coast and EA1N is located approximately 36 km off the coast at the nearest point to shore. The locations of the wind farms are shown in Figure 1-1. The proposed projects would have a potential capacity of up to 900 MW (EA2) and 800 MW (EA1N).

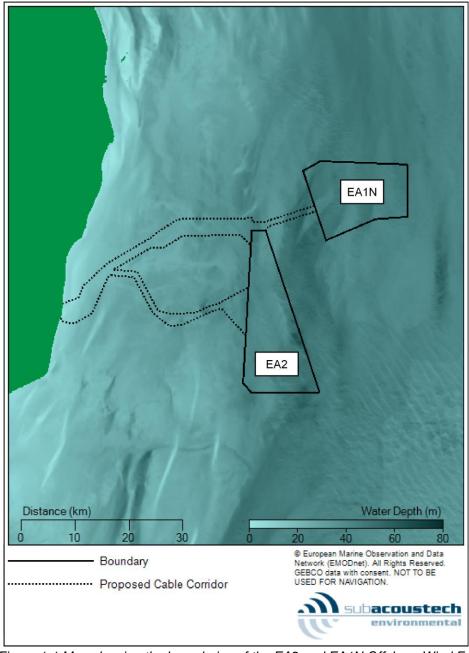

Figure 1-1 Map showing the boundaries of the EA2 and EA1N Offshore Wind Farm projects

1.2 Noise assessment

This report focuses on pile driving activities during construction at the EA2 and EA1N sites, and also considers other noise sources that are likely to be present during the development. Underwater noise modelling has been carried out in two parts. Impact piling has been considered using Subacoustech's INSPIRE (Impulse Noise Sound Propagation and Impact Range Estimator) subsea noise propagation and prediction software. Other noise sources have been considered using a high-level, simple modelling approach.

1.2.1 Impact piling

Impact piling has been proposed as a method for installing foundation piles for wind turbines into the seabed. It could be used to install either monopile or pin pile (jacket) foundation options.

The impact piling technique involves a large weight or "ram" being dropped or driven onto the top of the pile, forcing it into the seabed. Usually, double-acting hammers are used in which a downward force on the ram is applied, exerting a larger force than would be the case if it were only dropped under the action of gravity. Impact piling has been established as a source of high-level underwater noise (Würsig *et al.*, 2000; Caltrans, 2001; Nedwell *et al.*, 2003b and 2007; Parvin *et al.*, 2006; and Thomsen *et al.*, 2006).

Noise is created in air by the hammer as a direct result of the impact of the hammer with the pile and some of this airborne noise is transmitted into the water. Of more significance to the underwater noise is the direct radiation of noise from the pile into the water because of the compressional, flexural or other complex structural waves that travel down the pile following the impact of the hammer on the top. Structural pressure waves in the submerged section of the pile transmit sound efficiently into the surrounding water. These waterborne pressure waves will radiate outwards, usually providing the greatest contribution to the underwater noise.

1.2.2 Other source of noise

Although impact piling is expected to be the greatest noise source of noise during construction (Bailey *et al.* 2014, Bergström *et al.* 2014), several other noise sources associated with the wind farm development may also be present. These include UXO (unexploded ordnance) detonation, dredging, drilling, cable laying, rock placement, trenching, vessel noise and noise from operational wind turbines. These noise sources have been considered using a simple modelling approach due to the relative levels of noise and available information from these activities.

1.3 Scope of work

This report presents a detailed assessment of the potential underwater noise from impact piling at EA2 and EA1N and covers the following:

- A review of information on the units for measuring and assessing underwater noise and a review of underwater noise metrics and criteria that have been used to assess possible environmental effects in marine receptors (Section 2);
- A brief discussion of baseline ambient noise (Section 3);
- Discussion of the approach, input parameters and assumptions for the impact piling noise modelling undertaken (Section 4);
- Presentation of detailed subsea noise modelling using unweighted metrics (Section 5.1) and interpretation of the subsea noise modelling results with regards to injury and behavioural effects in marine mammals and fish using various noise metrics and criteria (Section 5.2);

- Summary of the predicted noise levels from the simple modelling approach for UXO detonation, dredging, drilling, cable laying, rock placement, trenching, vessel noise and noise from operational wind turbines (Section 6); and
- Summary and conclusions (Section 7).

An appendix of additional impact piling noise modelling, covering 75% and 50% of the full piling hammer energy, has also been included as Appendix A.

2 Measurement of noise

2.1 Underwater noise

Sound travels much faster in water (approximately 1,500 ms⁻¹) than in air (340 ms⁻¹). Since water is a relatively incompressible, dense medium, the pressures associated with underwater sound tend to be much higher than in air. As an example, background noise levels in the sea of 130 dB re 1 µPa for UK coastal waters are not uncommon (Nedwell *et al.*, 2003a and 2007). It should be noted that stated underwater noise levels should not be confused with the noise levels in air, which use a different scale.

2.1.1 Units of measurement

Sound measurements underwater are usually expressed using the decibel (dB) scale, which is a logarithmic measure of sound. A logarithmic scale is used because rather than equal increments of sound having an equal increase in effect, typically a constant ratio is required for this to be the case. That is, each doubling of sound level will cause a roughly equal increase in "loudness".

Any quantity expressed in this scale is termed a "level". If the unit is sound pressure, expressed on the dB scale, it will be termed a "Sound Pressure Level". The fundamental definition of the dB scale is given by:

$$Level = 10 \times \log_{10} \left(\frac{Q}{Q_{ref}} \right)$$

where Q is the quantity being expressed on the scale, and Q_{ref} is the reference quantity.

The dB scale represents a ratio and, for instance, 6 dB really means "twice as much as...". It is, therefore, used with a reference unit, which expresses the base from which the ratio is expressed. The reference quantity is conventionally smaller than the smallest value to be expressed on the scale, so that any level quoted is positive. For instance, a reference quantity of 20 μ Pa is used for sound in air, since this is the threshold of human hearing.

A refinement is that the scale, when used with sound pressure, is applied to the pressure squared rather than the pressure. If this were not the case, when the acoustic power level of a source rose by 10 dB the Sound Pressure Level would rise by 20 dB. So that variations in the units agree, the sound pressure must be specified in units of root mean square (RMS) pressure squared. This is equivalent to expressing the sound as:

Sound Pressure Level =
$$20 \times \log_{10} \left(\frac{P_{RMS}}{P_{ref}} \right)$$

For underwater sound, typically a unit of one micropascal (1 μ Pa) is used as the reference unit; a Pascal is equal to the pressure exerted by one Newton over one square metre; one micropascal equals one millionth of this.

Unless otherwise defined, all noise levels in this report are referenced to 1 μPa .

2.1.2 Sound pressure level (SPL)

The sound pressure level (SPL) is normally used to characterise noise and vibration of a continuous nature such as drilling, boring, continuous wave sonar, or background sea and river noise levels. To calculate the SPL, the variation in sound pressure is measured over a specific period to determine the Root Mean Square (RMS) level of the time varying sound. The SPL can therefore be considered a measure of the average unweighted level of sound over the measurement period.

Where SPL is used to characterise transient pressure waves such as that from seismic airguns, underwater blasting or impact piling, it is critical that the period over which the RMS level is calculated is quoted. For instance, in the case of a pile strike lasting, say, a tenth of a second, the mean taken

over a tenth of a second will be ten times higher than the mean spread over one second. Often, transient sounds such as these are quantified using "peak" SPLs.

2.1.3 Peak sound pressure level (SPL_{peak})

Peak SPLs are often used to characterise sound transients from impulsive sources, such as percussive impact piling and seismic airgun sources. A peak SPL is calculated using the maximum variation of the pressure from positive to zero within the wave. This represents the maximum change in positive pressure (differential pressure from positive to zero) as the transient pressure wave propagates.

A further variation of this is the peak-to-peak SPL where the maximum variation of the pressure from positive to negative within the wave is considered. Where the wave is symmetrically distributed in positive and negative pressure, the peak-to-peak level will be twice the peak level, or 6 dB higher (see 2.1.1).

2.1.4 Sound exposure level (SEL)

When assessing the noise from transient sources such as blast waves, impact piling or seismic airgun noise, the issue of the duration of the pressure wave is often addressed by measuring the total acoustic energy (energy flux density) of the wave. This form of analysis was used by Bebb and Wright (1953, 1954a, 1954b and 1955) and later by Rawlins (1987) to explain the apparent discrepancies in the biological effect of short and long-range blast waves on human divers. More recently, this form of analysis has been used to develop criteria for assessing the injury range from fish for various noise sources (Popper *et al.*, 2014).

The sound exposure level (SEL) sums the acoustic energy over a measurement period, and effectively takes account of both the SPL of the sound source and the duration the sound is present in the acoustic environment. Sound Exposure (SE) is defined by the equation:

$$SE = \int_{0}^{T} p^{2}(t)dt$$

where p is the acoustic pressure in Pascals, T is the duration of the sound in seconds, and t is the time in seconds. The SE is a measure of acoustic energy and has units of Pascal squared seconds (Pa²s).

To express the SE on a logarithmic scale by means of a dB, it is compared with a reference acoustic energy level (p_{ref}^2) and a reference time (T_{ref}). The SEL is then defined by:

$$SEL = 10 \times \log_{10} \left(\frac{\int_0^T p^2(t)dt}{P^2_{ref} T_{ref}} \right)$$

By selecting a common reference pressure P_{ref} of 1 μ Pa for assessments of underwater noise, the SEL and SPL can be compared using the expression:

$$SEL = SPL + 10 \times \log_{10} T$$

where the *SPL* is a measure of the average level of broadband noise, and the *SEL* sums the cumulative broadband noise energy.

This means that, for continuous sounds of less than one second, the SEL will be lower than the SPL. For periods greater than one second the SEL will be numerically greater than the SPL (i.e. for a continuous sound of ten seconds duration, the SEL will be 10 dB higher than the SPL, for a sound of 100 seconds duration the SEL will be 20 dB higher than the SPL, and so on).

Weighted metrics for marine mammals have been proposed by the National Marine Fisheries Service (NMFS) (2018) and Southall *et al.* (2007). These assign a frequency response to groups of marine mammals and are discussed in detail in the following section.

2.2 Analysis of environmental effects

2.2.1 Background

Over the past 20 years it has become increasingly evident that noise from human activities in and around underwater environments can have an impact on the marine species in the area. The extent to which intense underwater sound might cause an adverse impact in a species is dependent upon the incident sound level, sound frequency, duration of exposure and/or repetition rate of an impulsive sound (see for example Hastings and Popper, 2005). As a result, scientific interest in the hearing abilities of aquatic species has increased. Studies are primarily based on evidence from high level sources of underwater noise such as blasting or impact piling, as these sources are likely to have the greatest immediate environmental impact and therefore the clearest observable effects, although there has been more interest in chronic noise exposure over the last five years.

The impacts of underwater sound on marine species can be broadly summarised as follows:

- Physical traumatic injury and fatality;
- Auditory injury (either permanent or temporary); and
- Disturbance.

The following sections discuss the agreed criteria for assessing these impacts in species of marine mammal and fish at EA2 and EA1N.

2.2.2 Criteria to be used

The main metrics and criteria that have been used in this study to assess environmental effect come from several key papers covering underwater noise and its effects:

- The National Marine Fisheries Service guidance (NMFS, 2018) for marine mammals;
- The Southall et al. (2007) marine mammal noise exposure criteria;
- Data from Lucke et al. (2009) regarding harbour porpoise response to underwater noise;
- Sound exposure guidelines for fishes by Popper et al. (2014).

At the time of writing, these include the most up to date and authoritative criteria for assessing environmental effects for use in impact assessments. The NMFS (2018) document effectively updates Southall *et al.* (2007) but for completeness, both sets of criteria have been used. These are described in the following section.

2.2.2.1 Marine mammals

This assessment considers three sets of criteria to assess the effects of impact piling noise on marine mammals: NMFS (2018), Southall *et al.* (2007) and Lucke *et al.* (2009).

NMFS (2018) was co-authored by many of the same authors from the Southall *et al.* (2007) paper, and effectively updates its criteria for assessing the risk of auditory injury.

The NMFS (2018) guidance groups marine mammals into groups of similar species and applies filters to the unweighted noise to approximate the hearing sensitivity of the receptor. The hearing groups given in the NMFS (2018) are summarised in Table 2-1 and Figure 2-1. A further group for Otariid Pinnipeds is also given in the guidance for sea lions and fur seals but this has not been used in this study as those species of pinnipeds are not found in the North Sea.

Hearing group	Generalised hearing range	Example species
Low Frequency (LF) Cetaceans	7 Hz to 35 kHz	Baleen Whales
Mid Frequency (MF) Cetaceans	150 Hz to 160 kHz	Dolphins, Toothed Whales, Beaked Whales, Bottlenose Whales (including Bottlenose Dolphin)
High Frequency (HF) Cetaceans	275 Hz to 160 kHz	True Porpoises (including Harbour Porpoise
Phocid Pinnipeds (PW) (underwater)	50 Hz to 86 kHz	True Seals (including Harbour Seal)

Table 2-1 Marine mammal hearing groups (from NMFS, 2018)

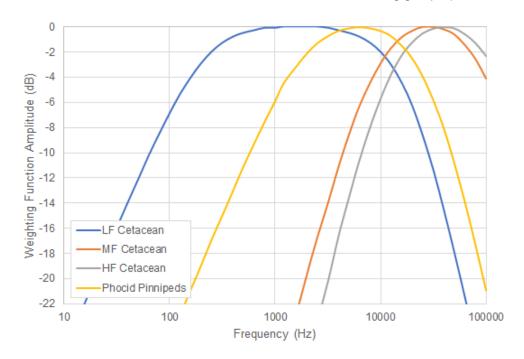

Figure 2-1 Auditory weighting functions for low frequency (LF) cetaceans, mid frequency (MF) cetaceans, high frequency (HF) cetaceans and phocid pinnipeds (PW) (underwater) (from NMFS, 2018)

NMFS (2018) also gives individual criteria based on whether the noise source is considered impulsive or non-impulsive. NMFS (2018) categorises impulsive noise as having high peak sound pressure, short duration, fast rise-time and broad frequency content at source, and non-impulsive sources as steady-state noise. Explosives, impact piling and seismic airguns are considered impulsive sources and sonars, vibropiling and other low-level continuous noises are considered non-impulsive. A non-impulsive sound does not necessarily have to have long duration.

NMFS (2018) presents single strike, unweighted peak criteria (SPL_{peak}) and cumulative (i.e. more than a single sound impulse), weighted sound exposure criteria (SEL_{cum}) for both permanent threshold shift (PTS) where unrecoverable hearing damage may occur and temporary threshold shift (TTS) where a temporary reduction in hearing sensitivity may occur in individual receptors. In addition, this study also includes weighted single strike sound exposure levels (SEL_{ss}).

Table 2-2 and Table 2-3 presents the NMFS (2018) criteria for onset of risk of PTS and TTS for each of the key marine mammal hearing groups considering impulsive and non-impulsive noise sources.

NU 150 (00 (0)	Unweighted SPL _{peak} (dB re 1 µPa)			
NMFS (2018)	Impulsive			
	PTS	TTS

Table 2-3 SEL_{cum} and SEL_{ss} criteria for assessment of PTS and TTS in marine mammals (NMFS, 2018)

Southall *et al.* (2007) has been the source of the most widely used criteria to assess the effects of noise on marine mammals since it was published, although has largely been superseded by NMFS (2018). The criteria from Southall *et al.* (2007) are based on M-Weighted SELs, which are generalised frequency weighting functions to adjust underwater noise data to better represent the levels of underwater noise that various marine species are likely to be able to hear; it is worth noting that M-Weightings differ from the weightings used in NMFS (2018). The authors group marine mammals into five groups, four of which are relevant to underwater noise (the fifth is for pinnipeds in air). For each group, an approximate frequency range of hearing is proposed based on known audiogram data, where available, or inferred from other information such as auditory morphology. The M-Weighting filters are summarised in in Table 2-4 and Figure 2-2.

Functional hearing group	Established auditory bandwidth	Genera represented	Example species
Low frequency (LF) cetaceans	7 Hz to 22 kHz	Balaena, Caperea, Eschrichtius, Megaptera, Balaenoptera (13 species/subspecies)	Humpback whale, minke whale
Mid frequency (MF) cetaceans	150 Hz to 160 kHz	Steno, Sousa, Sotalia, Tursiops, Stenella, Delphinus, Lagenodelphis, Lagenorhynchus, Lissodelphis, Grampus, Peponocephala, Feresa, Pseudorca, Orcinus, Globicephala, Orcaella, Physeter, Delphinapterus, Monodon, Ziphius, Berardius, Tasmacetus, Hyperoodon, Mesoplodon (57 species/subspecies)	Bottlenose dolphin, white-beaked dolphin, killer whale, sperm whale
High frequency (HF) cetaceans	200 Hz to 180 kHz	Phocoena, Neophocaena, Phocoenoides, Platanista, Inia, Kogia, Lipotes, Pontoporia, Cephalorhynchus (20 species/subspecies)	Harbour porpoise
Pinnipeds (in water)	75 Hz to 75 kHz	Arctocephalus, Callorhinus, Zalophus, Eumetopias, Neophoca, Phocarctos, Otaria, Erignathus, Phoca, Pusa, Halichoerus, Histriophoca, Pagophilus, Cystophora, Monachus, Mirounga, Leptonychotes, Ommatophoca, Lobodon, Hydrurga, Odobenus (41 species/subspecies)	Harbour (common) seal, grey seal

Table 2-4 Functional marine mammal groups, their assumed auditory bandwidth of hearing and genera presented in each group (from Southall et al., 2007)

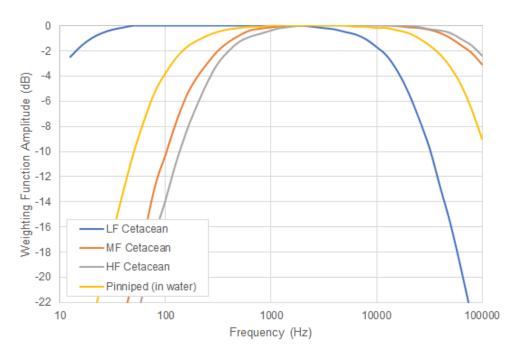

Figure 2-2 Auditory M-weighting functions for low frequency (LF) cetacean, mid frequency (MF) cetacean, high frequency (HF) cetacean and pinniped (in water) (underwater) (from Southall et al. 2007)

The unweighted SPL_{peak} and M-Weighted SEL criteria used in this study are summarised in Table 2-5 to Table 2-7, covering auditory injury, TTS and behavioural avoidance for both impulsive and non-impulsive noise sources. It should be noted that for this study the SEL criteria for both multiple pulse (SEL_{cum}) and single pulse (SEL_{ss}) have been used.

Southall et al. (2007)	Unweighted SPL _{peak} (dB re 1 µPa) Impulsive Auditory Injury TTS		
Low Frequency (LF) Cetaceans	230	224	
Mid Frequency (MF) Cetaceans	230	224	
High Frequency (HF) Cetaceans	230	224	
Pinnipeds (in water) (PW)	218	212	

Table 2-5 SPL_{peak} criteria for assessment of auditory injury and TTS in marine mammals (Southall et al, 2007)

	M-Weighted SEL _{cum} and SEL _{ss} (dB re 1 μPa ² s)			
Southall et al.	Impu	Non-impulsive		
(2007)	Auditory injury	TTS (SEL _{ss} only)	Auditory injury	
Low Frequency (LF) Cetaceans	198	183	215	
Mid Frequency (MF) Cetaceans	198	183	215	
High Frequency (HF) Cetaceans	198	183	215	
Pinnipeds (in water) (PW)	186	171	203

Southall et al.	Unweighted SEL _{ss} (dB re 1 µPa ² s)		
(2007)	Likely	Possible	
(2007)	Avoidance	Avoidance	
Low Frequency	152	142	
(LF) Cetaceans	132	142	
Mid Frequency (MF) Cetaceans	170	160	

Table 2-7 Criteria for assessment of behavioural avoidance in marine mammals (Southall et al, 2007)

In addition to Southall *et al.* (2007), criteria from Lucke *et al.* (2009) have been used to further assess the effects of noise on harbour porpoise. The criteria from Lucke *et al.* (2009) are derived from testing harbour porpoise hearing thresholds before and after being exposed to seismic airgun stimuli (a pulsed noise like impact piling). All the criteria used are unweighted single strike (SEL_{ss}). These are summarised in Table 2-8. These are included for completeness; use of the NMFS (2018) criteria is recommended as a preference.

Lucko ot ol	Unweighted SEL _{ss} (dB re 1 μPa ² s)			
Lucke <i>et al.</i> (2009)	Impulsive			
(2009)	Auditory Injury	TTS	Behavioural	
Harbour Porpoise	179	164	145	

Table 2-8 Criteria for assessment of auditory injury, TTS and behavioural response in harbour porpoise (Lucke et al, 2009)

Where SEL_{cum} are required, a fleeing animal model has been used. This assumes that the animal exposed to high noise levels will swim away from the noise source. For this a constant fleeing speed of 3.25 ms⁻¹ has been assumed for the low frequency (LF) cetaceans group (Blix and Folkow, 1995), based on data for minke whale, and for other receptors a constant rate of 1.5 ms⁻¹ has been assumed, which is a cruising speed for a harbour porpoise (Otani *et al.*, 2000). These are considered 'worst case' as

marine mammals are expected to be able to swim much faster under stress conditions. The model assumes that when a fleeing receptor reaches the coast it receives no more noise, as it is likely that the receptor will flee along the coast, and at this distance from EA2 and EA1N sites the receptor will be far enough from the piling that it will have received the majority of its noise exposure.

This assessment is comprehensive in its inclusion of the criteria from NMFS (2018) as well as the older Southall *et al.* and Lucke *et al.* (2009) criteria.

2.2.2.2 Fish

The large number of and variation in fish species leads to a greater challenge in production of a generic noise criterion, or range of criteria, for the assessment of noise impacts. Whereas previous assessments applied broad criteria based on limited studies of fish not present in UK waters (e.g. McCauley *et al.*, 2000), the publication of Popper *et al.* (2014) provides an authoritative summary of the latest research and guidelines for the assessment of fish exposure to sound and uses categories for fish that are representative of the species present in UK waters.

The Popper *et al.* (2014) study groups species of fish into whether they possess a swim bladder, and whether it is involved in its hearing. The guidance also gives specific criteria (as both SPL_{peak} and SEL_{cum} values) for a variety of noise sources; in this case impact piling, explosions (for UXO) and continuous noise have been considered. As with the marine mammal criteria, SEL_{ss} values have been considered alongside the SEL_{cum} criteria.

The criteria used for modelling are summarised in Table 2-9 to Table 2-11. In a similar fashion to marine mammals for SEL_{cum} results, a fleeing animal model has been used assuming a fish flees from the source at a constant rate of 1.5 ms⁻¹, based on data from Hirata (1999). This speed is the slowest of all species identified. This is discussed further, below.

	Mortality and	Impairment		
Impact piling	potential mortal injury	Recoverable injury	TTS	
Fish: no swim bladder	>219 dB SEL _{cum} or >213 dB SPL _{peak}	>216 dB SEL _{cum} or >213 dB SPL _{peak}	>>186 dB SELcum	
Fish: swim bladder is not involved in hearing	210 dB SEL _{cum} or >207 dB SPL _{peak}	203 dB SEL _{cum} or >207 dB SPL _{peak}	>186 dB SEL _{cum}	
Fish: swim bladder involved in hearing	207 dB SEL _{cum} or >207 dB SPL _{peak}	203 dB SEL _{cum} or >207 dB SPL _{peak}	186 dB SELcum

Table 2-11 Criteria for assessment of recoverable injury and TTS in species of fish from continuous noise sources (Popper et al, 2014)

A further set of criteria also exists for turtles and fish eggs and larvae; however, these have not been considered as part of this study. Where insufficient data is available, Popper *et al.* (2014) give qualitative criteria that summarise the effect of the noise as having either a high, moderate or low effect on an individual in either the near-filed (tens of metres), intermediate-field (hundreds of metres), or far-field (thousands of metres). These qualitative effects are reproduced in Table 2-12 to Table 2-14.

Table 2-14 Summary of the qualitative effects on fish from continuous noise from Popper et al. (2014)

(N=Near-field, I=Intermediate-field, F=Far-field)

A fleeing animal model has been used for fish. It is recognised that there is limited evidence for fish fleeing from high noise sources in the wild and it would reasonably be expected that the reaction would differ between species; most species are likely to move away from a sound that is loud enough to cause harm (Dahl *et al.* (2015), Popper *et al.* (2014)), some may seek protection in the sediment and others may dive deeper in the water column. The flee speed of 1.5 ms⁻¹ is relatively slow in relation to the data in Hirata (1999) and thus is somewhat conservative.

Although it is feasible that some species will not flee, those that are likely to remain are thought to more likely be benthic species or without a swim bladder; these are the least sensitive species. For example, from Popper *et al.* (2014): "There is also evidence (e.g., Goertner *et al.* 1994; Stephenson *et al.* 2010; Halvorsen *et al.* 2012) that little or no damage occurs to fishes without a swim bladder except at very short ranges from an in-water explosive event. Goertner (1978) showed that the range from an explosive event over which damage may occur to a non-swim bladder fish is on the order of 100 times less than that for swim bladder fish."

Therefore, basing the assessment on a stationary (zero flee speed) receptor is likely to greatly overestimate the potential risk to fish species, especially when considering the precautionary nature of the parameters already built into the cumulative exposure model.

3 Baseline Ambient Noise

The baseline noise level in open water, in the absence of any specific anthropogenic noise source, is generally dependent on a mix of the movement of the water and sediment, weather conditions and shipping. There is a component of biological noise from marine mammal and fish vocalisation, as well as an element from invertebrates.

Outside of the naturally occurring ambient noise, man-made noise dominates the background. The North Sea is heavily shipped by fishing, cargo and passenger vessels, which contribute to the ambient noise in the water. The larger vessels are not only louder but the noise tends to have a lower frequency, which travels more readily, especially in the deeper open water. Other vessels such as dredgers and small fishing boats have a lower overall contribution. There are no dredging areas, Active Dredge Zones or Dredging Application Option and Prospecting Areas within the EA2 and EA1N offshore project area.

Other sources of anthropogenic noise include oil and gas platforms and other drilling activity, clearance of unexploded ordnance (UXO) and military exercises. Drilling may contribute some low frequency noise in the wind farm site, although due to its low-level nature (see section 6) this is unlikely to contribute to the overall ambient noise. Clearance of UXO contributes high but infrequent noise. Little information is available on the scope and timing of military exercises, but they are not expected to last for an extended period, and so would have little contribution to the long-term ambient noise in the area.

The Marine Strategy Framework Directive requires European Union members to ascertain baseline noise levels by 2020, and monitoring processes are being put into place for this around Europe. Good quality, long-term underwater noise data for the region is not currently available.

Typical underwater noise levels show a frequency dependency in relation to different noise sources; the classic curves are given in Wenz (1962) and are reproduced in Figure 3-1 below. Figure 3-1 shows that any unweighted overall (i.e. single-figure non-frequency-dependent) noise level is typically dependent on the very low frequency element of the noise. The introduction of a nearby anthropogenic noise source (such as piling or sources involving engines) will tend to increase the noise levels in the 100-1000 Hz region, but to a lesser extent will also extend into higher and lower frequencies.

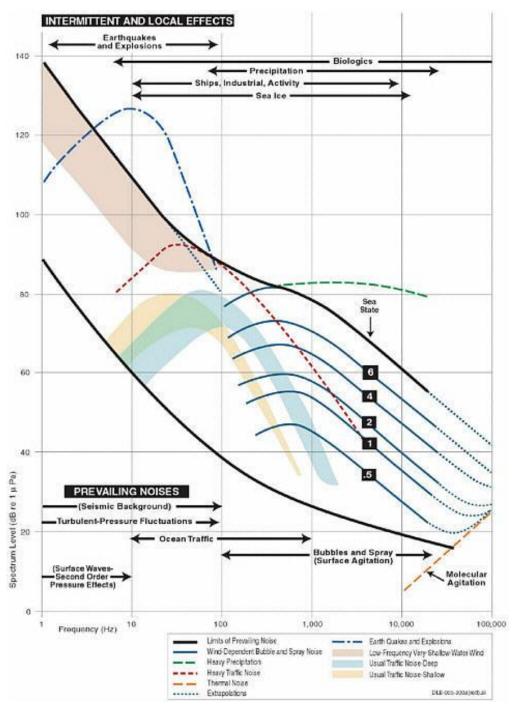

Figure 3-1 Ambient underwater noise following Wenz (1962) showing frequency dependency from different noise sources.

In 2011, around the time of the met-mast installation in the former Hornsea zone, also in the North Sea, snapshot baseline underwater noise levels were sampled as part of the met-mast installation noise survey (Nedwell and Cheesman, 2011). Measurements were taken outside of the installation activity and in the absence of any nearby vessel noise. This survey sampled noise levels of 112 to 122 dB re 1 μ Pa RMS over two days and were described as not unusual for the area. The higher figure was due to higher sea state on that day. Unweighted overall noise levels of this type should be used with caution without access to more detail regarding the duration, frequency content and conditions under which the sound was recorded, although they do demonstrate an indication of the natural variation in background noise levels.

There is little additional, documented ambient noise data publicly available for the region. Merchant *et al.* (2014) measured underwater ambient noise in the Moray Firth, acquiring measurements of a similar order to the baseline snapshot levels noted above, and which showed significant variation (i.e. a 60 dB spread) in daily average noise levels. Although this is outside of the region and in a much more coastal and heavily shipped location, it demonstrates that the snapshot noted above gives only limited information as the average daily noise levels are so dependent on weather and local activity. However, the snapshot measurements taken do show noise levels that are of the same order as baseline noise levels sampled elsewhere in the North Sea (Nedwell *et al.*, 2003a) and so are considered to be realistic.

In principle, when noise introduced by anthropogenic sources propagates far enough it will reduce to the level of ambient noise, at which point it can be considered negligible. In practice, as the underwater noise thresholds defined in section 2.2.2 are all considerably above the level of background noise, any noise baseline would not feature in an assessment to these criteria.

4 Impact piling modelling methodology

4.1 Modelling introduction

To estimate the underwater noise levels likely to arise during construction of EA2 and EA1N, predictive noise modelling has been undertaken. The methods described in this section, and utilised within this report, meet the requirements set by the NPL Good Practice Guide 133 for underwater noise measurement (Robinson *et al.*, 2014).

The modelling has been undertaken using the INSPIRE noise model. The INSPIRE model (currently version 4.0) is a semi-empirical underwater noise propagation model based around a combination of numerical modelling and actual measured data. It is designed to calculate the propagation of noise in shallow, mixed water, typical of the conditions around the UK and very well suited to the EA2 and EA1N sites. The model has been tuned for accuracy using over 50 datasets of underwater noise propagation around offshore piling.

The model provides estimates of unweighted SPL_{peak}, SEL_{ss}, and SEL_{cum} noise levels as well as various other weighted noise metrics. Calculations are made along 180 equally spaced radial transects (one every 2°). For each modelling run a criterion level can be specified allowing a contour to be drawn, within which a given effect may occur. These results are then plotted over digital bathymetry data so that impact ranges can be clearly visualised and assessed as necessary.

INSPIRE considers a wide array of input parameters, including variations in bathymetry and source frequency content to ensure accurate results for the circumstances. It should also be noted that the results presented in this study should be considered conservative as worst-case parameters have been selected for:

- · Piling hammer blow energies;
- Soft start ramp-up profile and strike rate;
- Duration of piling; and
- · Receptor swim speeds.

The input parameters for the modelling are detailed in the following section.

4.2 Locations

Modelling has been undertaken at two representative locations at each wind farm site, covering the worst-case (WC) position (i.e. the deepest location where piling can take place, which tends to give the greatest noise propagation), and an average water depth (AV) location located in slightly shallower water. The chosen locations are shown in Figure 4-1 and summarised in Table 4-1, below.

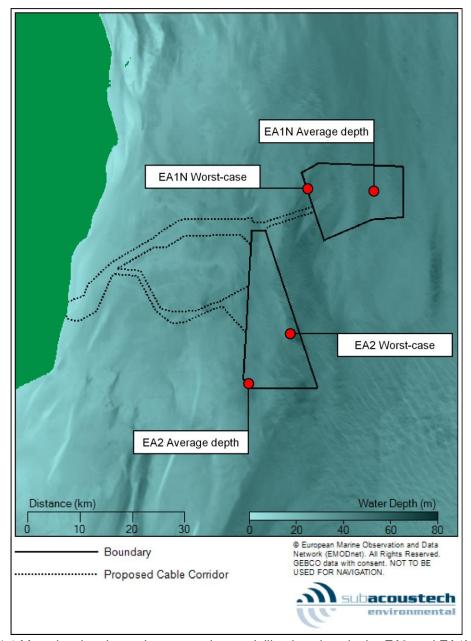

Figure 4-1 Map showing the underwater noise modelling locations in the EA2 and EA1N OWF sites

	EA2		EA1N	
	Worst-case	Average depth	Worst-case	Average depth
Latitude	52.1423°N	52.0564°N	52.3916°N	52.3864°N
Longitude	002.2541°E	002.1369°E	002.3023°E	002.4882°E
Water depth	55 m	47.5 m	55 m	45 m

Table 4-1 Summary of the underwater noise modelling locations and associated water depths (mean tide)

4.3 Input parameters

The modelling takes full account of the environmental parameters within the study area and the characteristics of the noise source. The following parameters have been assumed for modelling.

4.3.1 Impact piling parameters

Two piling source scenarios have been modelled to include monopile and pin pile (jacket) WTG (wind turbine generator) foundations across the EA2 and EA1N OWF farm sites. These are:

- Monopiles, up to 15 m in diameter, installed using a maximum hammer blow energy of 4000 kJ;
 and
- Pin piles, up to 4.6 m in diameter installed using a maximum hammer blow energy of 2400 kJ.

For cumulative SELs, the soft start and ramp up of blow energies along with total duration and strike rate of the piling have also been considered. These are summarised in Table 4-2 to Table 4-3, below. The soft start and ramp ups take place over the first half-hour of piling, starting at ten percent of maximum and gradually increasing in blow energy to 80% before reaching the maximum energy and strike rate, where it stays for the remaining time.

The monopile scenario contains 9,300 pile strikes over 325 minutes (5 hours 25 minutes, inclusive of soft start and ramp up), the pin pile scenario contains 7210 pile strikes over 199 minutes (3 hours 19 minutes).

	Soft start (10%)	Ramp up to 80%	Main piling (100%)
Monopile blow energy	400 kJ	Gradual increase	4000 kJ
Number of strikes	150 strikes	300 strikes	8850 strikes
Duration	10 minutes	20 minutes	295 minutes
Strike rate	15 strikes	30 strikes per minute	

Table 4-2 Summary of the ramp up scenario used for calculating cumulative SELs for monopiles

	Soft start (10%)	Ramp up to 80%	Main piling (100%)
Pin pile blow energy	240 kJ	Gradual increase	2400 kJ
Number of strikes	150 strikes	300 strikes	6760 strikes
Duration	10 minutes	20 minutes	169 minutes
Strike rate	15 strikes	40 strikes per minute	

Table 4-3 Summary of the ramp up scenario used for calculating cumulative SELs for a single pin pile

At the time of reporting a driveability study has not been completed, and as such additional modelling runs have been undertaken to assess noise levels assuming the blow energy only reaches 75% and 50% of the maximum hammer blow energy during the main piling. Not reaching full power is a frequent occurrence during piling on site. The results of this modelling are presented in Appendix A along with a comparison to the 100% maximum hammer blow energy results.

4.3.2 Source levels

Noise modelling requires knowledge of the source level, which is the theoretical noise level at 1 m from the noise source.

The INSPIRE noise propagation model assumes that the noise source, the hammer striking the pile, acts as a single point, as it will appear at a distance. This is then adjusted to take into account the water depth at the modelled source location to allow for the length of pile in contact with the water, which can affect the amount of noise that is transmitted from the pile into its surroundings. However, as the water depths for the modelling locations considered for this study are all in excess of 45 m, the source levels do not alter with location.

The unweighted single strike SPL_{peak} and SEL_{ss} source levels estimated for this project are provided in Table 4-4 and Table 4-5.

		SPL _{peak} source level	SEL _{ss} source level
Monopile	10% (400kJ)	235.4 dB re 1 μPa @ 1 m	219.0 dB re 1 µPa ² s @ 1 m
Monophe	100% (4000kJ)	239.6 dB re 1 μPa @ 1 m	223.3 dB re 1 µPa ² s @ 1 m

Table 4-4 Summary of the unweighted single strike source levels used for modelling monopiles in this study

		SPL _{peak} source level	SEL _{ss} source level
Din nile	10% (240kJ)	233.1 dB re 1 μPa @ 1 m	216.8 dB re 1 µPa ² s @ 1 m
Pin pile	100% (2400kJ)	239.2 dB re 1 µPa @ 1 m	222.9 dB re 1 µPa ² s @ 1 m

Table 4-5 Summary of the unweighted single strike source levels used for modelling pin piles in this study

4.3.3 Frequency content

The size of the pile being installed affects the frequency content of the noise it produces. For this modelling, frequency data has been sourced from Subacoustech's noise measurement database and an average taken to obtain representative 1/3-octave band frequency spectrum levels (i.e. the frequency break-down of a noise level) for installing monopiles and pin piles. The 1/3-octave band levels for maximum hammer energy used for modelling are illustrated in Figure 4-2; the shape of each spectrum is the same for all the other locations and blow energies, with the overall source levels adjusted depending on these parameters. This is particularly important when considering marine mammal species that are more sensitive to a particular frequency of sound than others.

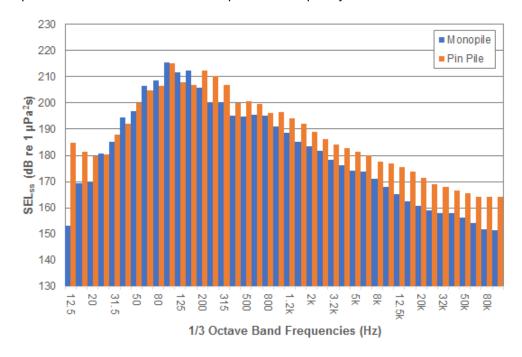

Figure 4-2 1/3-octave source level frequency spectra for the maximum hammer blow energy

Frequency spectra for piles of 7 m in diameter, the largest with measured data available, has been used for the monopile modelling and piles of approximately 4 m in diameter (near the top end of the pin pile options being considered) have been used for pin pile modelling. It is worth noting that the monopiles contain more low frequency content and the pin piles contain more high frequency content, due to the acoustics related to the dimensions of the pile. This trend would be expected to continue to larger piles under consideration for the monopiles at EA2 and EA1N. A larger diameter would be expected to move the dominant frequency of the sound (i.e. the frequency where the highest levels are present) produced lower, further below the frequencies of greatest hearing sensitivity of marine mammals. Thus, the sound would appear slightly quieter to a receptor more sensitive to higher frequencies, such as dolphins and

porpoises (MF and HF cetaceans) and the spectrum used is likely to be worst case. Marine mammal hearing sensitivity is covered in section 2.2.

4.3.4 Environmental conditions

Accurate modelling of underwater noise propagation requires knowledge of the sea and seabed conditions. The semi-empirical nature of the INSPIRE model considers the seabed type and speed of sound in water for the mixed conditions around the EA2 and EA1N site as it is based on over 50 datasets taken of impact piling noise in coastal and offshore waters surrounding the UK.

Mean tidal depth has been used for the depth of water across the site as the tidal state will fluctuate throughout installation of foundations.

4.4 Modelling confidence

Modelling has been undertaken using the latest iteration (version 4.0) of the INSPIRE modelling software.

As discussed in section 4.1, INSPIRE is a semi-empirical model based around a combination of numerical modelling and actual measured data. The INSPIRE model has always endeavoured to give a conservative estimate of underwater noise levels from impact piling noise. There is always some variability with underwater noise measurements, even when considering measurements of pile strikes at the same blow energy taken at the same range, there can still be big variations in noise level (sometimes up to 5 or even 10 dB) (for example, Bailey *et al.* (2010) and the data shown in Figure 4-3). The INSPIRE model is always compared to the highest of these measured noise levels at any range.

INSPIRE version 4.0 is the product of going back and re-analysing all the impact piling noise measurements in Subacoustech's measurement database and cross-referencing it with blow energy data from piling logs, giving a database of single strike noise levels referenced to a specific blow energy at various ranges. This re-analysis showed that the previous version of INSPIRE overestimated the change in noise level with blow energy, which in most cases lead to overestimations in predicted noise levels.

As the INSPIRE model is semi-empirical, a validation process is inherently built into the development process. Whenever a new set of good, reliable, impact piling measurement data is gathered through offshore surveys, it is compared against the outputted levels from INSPIRE. Currently, over 50 separate impact piling noise datasets from all around the UK have been used as part of development for the latest version of INSPIRE, and in each case, a conservative fit is used. This is the same process that has been used for the previous iterations of INSPIRE, however with each new version more measurement data is used.

In addition to this, INSPIRE is also validated by comparing the noise levels from the model with measurements and modelling undertaken by third parties.

Figure 4-3 presents a selection of example measured impact piling noise data plotted against outputs from INSPIRE version 4.0. The plots show data points from measured data (red points) plotted alongside modelled data (green points) using the INSPIRE version 4.0 model matching the pile size, blow energy and range of the measured data. These show the conservative fit to data with the data points from INSPIRE sitting at the upper end of the measured noise level at each range.

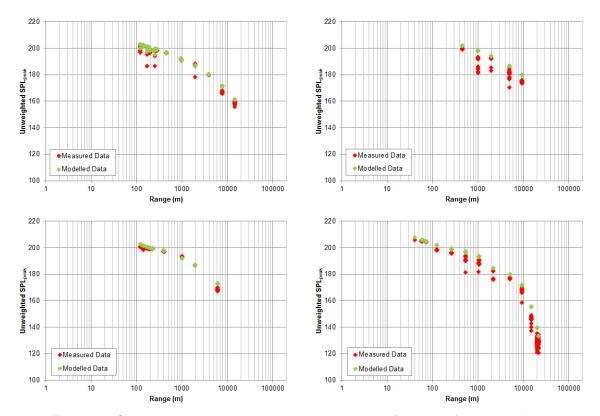

Figure 4-3 Comparison between example measured data (red points) and modelled data using INSPIRE version 4.0 (green points)

5 Impact piling noise modelling outputs

5.1 Unweighted subsea noise modelling

This section presents the unweighted noise level results (i.e. in the absence of any weighting applied for marine mammal hearing sensitivity) from the modelling undertaken for impact piling operations using the modelling parameters detailed in section 2.2.2.

The following figures present unweighted SPL_{peak} noise levels from impact piling operations at the EA2 and EA1N modelling locations shown in Figure 4-1.

Figure 5-1 to Figure 5-8 show the unweighted SPL_{peak} noise levels for monopiles (installed using a maximum blow energy of 4000 kJ) and the unweighted SPL_{peak} noise levels for pin piles (installed using a maximum blow energy of 2400 kJ).

Comparing these plots shows that, in general, the increased noise levels with no weighting applied, are expected to occur in deeper water. The effect of the deep water on noise transmission is also shown when considering the ridges to the southwest and northwest of the site, where a more 'jagged' contour occurs between the ridges on the seabed.

Due to the transient nature of impact piling noise, the impulsive noise introduced to the water will return to background levels within seconds of the impulse passing.

The noise levels on these plots, denoted in dB SPL_{peak}, should not be confused with background or ambient noise levels, which are typically described in terms of dB SPL_{RMS}. The two metrics are not directly comparable.

As discussed in section 4.3.1, results for the 75% and 50% maximum blow energy scenarios are presented as part of Appendix A.

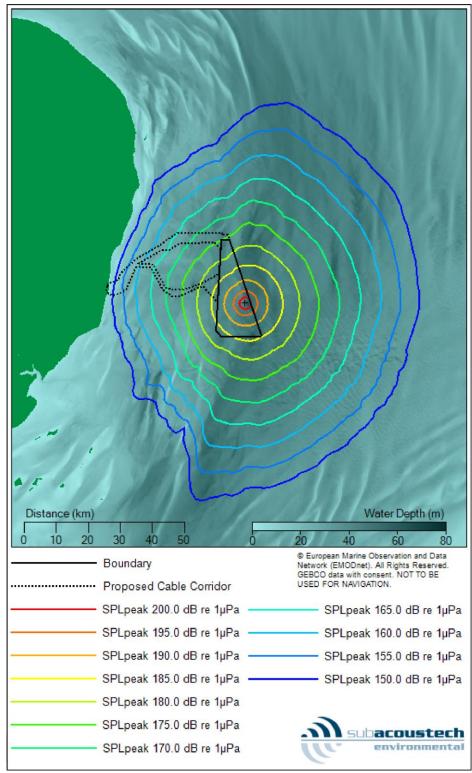

Figure 5-1 Noise level plot showing the predicted SPL_{peak} noise levels predicted for installing a monopile using a maximum blow energy of 4000 kJ at the worst-case location in EA2

5.2 Interpretation of results

This section presents the modelling results in terms of the noise metrics and criteria covered in section 2.2. This discussion will guide the assessment of environmental impact to marine species from the predicted impact piling noise. For all the results given in the following sections, ranges calculated to be less than 50 m for single strike criteria and 100 m for cumulative criteria have not been included as due to the uncertainty in the accuracy of the results at such close range. In this case the ranges are given as "<50m" or "<100m", in that the impact range will be closer to the pile than this distance.

5.2.1 Impacts on marine mammals

The following sections present the modelling results in biological terms for various species of marine mammal, separated by the guidance: NMFS (2018), Southall *et al.* (2007) and Lucke *et al.* (2009). As discussed in section 2.2.2.1, for the SEL_{cum} criteria, fleeing animal speeds of 3.25 ms⁻¹ (Blix and Folkow, 1995) for LF cetaceans and 1.5 ms⁻¹ (Otani *et al.* 2000) for other species of marine mammal have been used.

5.2.1.1 NMFS (2018) results

Table 5-1 to Table 5-16 present the predicted PTS and TTS impact ranges for the different marine mammal hearing groups using the NMFS (2018) thresholds. The criteria are given as unweighted SPL_{peak} or weighted SELs, of which both single strike (SEL_{ss}) and cumulative (SEL_{cum}) have been presented. Multiple pulse results include the noise exposure to a fleeing animal receptor over the entire installation period. SEL_{cum} are not calculated for the soft start, as this represents only the first strike of the piling process.

In line with the unweighted results shown in section 5.1, maximum SEL_{cum} ranges of 21 km predicted for PTS and 45 km predicted for TTS in LF and HF cetaceans at the worst-case modelling location for the EA1N site. It is worth noting that the SEL_{cum} results for pin piles are consistently larger than those for monopiles. This is primarily because of the faster strike rate assumed for installing pin piles (Table 4-2 and Table 4-3). The larger impact ranges for pin piles for MF and HF cetaceans are also caused by the frequencies filtered by the NMFS (2018) species group weightings (Table 2-1 and Figure 2-1). This is discussed further in section 5.2.1.1.3.

Results for the initial impact ranges for the first strike of the soft start (400 kJ for monopile and 240 kJ for pin pile) and for the maximum energy, including exposure over the entire piling sequence, are given in separate tables.

Table 5-16 Summary of the single strike and cumulative impact ranges for TTS from NMFS (2018) for installation of a pin pile at EA1N using the 100% maximum hammer blow energy of 2400 kJ

5.2.1.1.3 Discussion

The ranges of impact vary depending on the hearing (species) group and severity of impact. Looking at the monopile results from the worst-case modelling location at EA2 as an example (Table 5-2 and Table 5-6), the SEL results using the LF weighting lead to the greatest ranges as the MF and HF cetacean and pinniped weightings filter out much of the piling energy at lower frequencies. It is also

worth noting that greater ranges are created for the transects travelling through the deepest water. This is shown clearly in section 5.1.

This also explains why some of the ranges for the "worst case" piling locations are actually shorter than the "average depth" location. Although the source is in a slightly deeper position, the "average depth" location is closer to areas of deeper water, and so this can lead to more of the overall area around this location being at a slightly higher noise level, and thus the noise exposure being slightly greater overall.

The SEL_{cum} results show that larger ranges are expected for pin piles than for monopiles due to the faster strike rate assumed for those scenarios. Another factor that adds to this is the difference between the marine mammal hearing groups and the sound frequencies produced by the different piles.

The frequency spectra used as inputs to the model (Figure 4-2) show that the noise from pin piles contains more high frequency components than the noise from monopiles. The overall unweighted noise level is higher for the monopile due to the low frequency components of piling noise (i.e. most of the pile strike energy is in the lower frequencies). The MF and HF cetacean filters (Figure 2-1) both remove the low frequency components of the noise, as species in these marine mammal groups are much less sensitive to noise at these frequencies. This leaves the higher frequency noise, which, in the case of the pin piles, is higher than that for the monopiles.

To illustrate this, Figure 5-9 shows the sound frequency spectra for monopiles and pin piles, adjusted (weighted) to account for the sensitivities of MF and HF cetaceans. These can be compared to the original unweighted frequency spectra in Figure 4-2 (shown faintly in Figure 5-9). Overall, higher levels are present in the weighted pin pile spectrum.

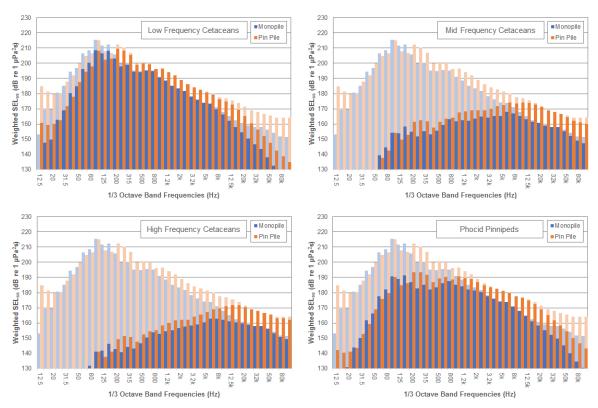

Figure 5-9 Filtered noise inputs for monopiles and pin piles using the NMFS (2018) filters. The lighter coloured bars show the unweighted third octave levels

5.2.1.2 Southall et al. (2007) results

Table 5-17 to Table 5-24 (EA2) and Table 5-29 to Table 5-36 (EA1N) present the predicted PTS and TTS impact ranges for various cetaceans and pinniped hearing groups based on the Southall *et al.*

(2007) thresholds for soft start and maximum energy including exposure over the entire installation of a pile. Behavioural avoidance results for low and mid frequency cetaceans are given in Table 5-25 to Table 5-28 (EA2) and Table 5-37 to Table 5-40 (EA1N). The behavioural response ranges for high frequency cetaceans are given using the Lucke *et al.* (2009) criteria in section 5.2.1.3.

Maximum PTS ranges for any species are predicted for pinnipeds (in water) of 7.5 km using the SEL_{cum} criteria from Southall *et al.* (2007) due to the more conservative criteria for pinnipeds compared to the cetacean hearing groups. Ranges out to a maximum of 51 km are also predicted for behavioural avoidance in LF cetaceans.

5.2.1.3 Lucke et al. (2009) results

Table 5-41 to Table 5-48 present the predicted impact ranges in terms of the criteria from Lucke *et al.* (2009), covering auditory injury, TTS and behavioural reaction in harbour porpoise. These criteria are defined in section 2.2.2.1. The criteria from Lucke *et al.* (2009) are all unweighted single strike SELs.

5.2.2 Impacts on fish

Table 5-49 to Table 5-72 give the maximum, minimum, and mean impact ranges for species of fish based on the injury criteria found in the Popper *et al.* (2014) guidance.

As discussed in section 2.2.2.2, for the SEL_{cum} criteria, a fleeing animal speed of 1.5 ms⁻¹ has been used (Hirata, 1999). All the impact thresholds from the Popper *et al.* (2014) guidance are unweighted. It should be noted that some of the same noise levels are used as criteria for multiple effects. This is as per the Popper *et al.* (2014) guidelines (shown in Table 2-9), which is based on a comprehensive literature review. The data available to create the criteria are very limited and most criteria are "greater than", with a precise threshold not identified. All ranges associated with criteria defined as ">" are therefore conservative and in practice the actual range at which an effect could occur will be somewhat lower. As with the marine mammal criteria, where impact ranges are less than 50 m (SPL_{peak}) and 100 m (SEL_{cum}); these are denoted < 50 m and < 100 m, without attempting to define ranges any more accurately.

The results show that fish with swim bladders involved in hearing are the most sensitive to the impact piling noise with ranges of up to a maximum of 500 m for the SPL_{peak} recoverable injury criteria and ranges up to 29 km for TTS (SEL_{cum}) for the pin pile scenarios. As with the modelling results presented in the previous sections, the largest SEL_{cum} ranges are predicted for pin piles due to the more rapid assumed strike rate.

6 Other noise impacts

6.1 Introduction

Although impact piling is expected to be the primary noise source during offshore wind farm construction and development (Bailey *et al.* 2014), several other noise sources will also be present. Each of these has been considered, and its impact assessed, in this section.

Table 6-1 provides a summary of the various noise producing sources, aside from impact piling, that are expected to be present during the construction and operation of EA2 and EA1N.

Activity	Description				
UXO detonation	Unexploded Ordnance (UXO) has been identified within the boundaries of EA2 and EA1N, which need to be cleared before construction can begin.				
Dredging	Trailer suction hopper dredger may be required on site for the export cable, array cable and interconnector cable installation.				
Drilling	Necessary in case if impact piling refusal				
Cable laying	Required during the offshore cable installation.				
Rock placement	Potentially required on site for installation of offshore cables and scour protection.				
Trenching	Plough trenching may be required during offshore cable installation.				
Vessel noise	Jack-up barges for piling, substructure and turbine installation. Other large and medium sized vessels on site to carry out other construction tasks, dive support and anchor handling. Other small vessels for crew transport and maintenance on site.				
Operational WTG	Noise transmitted through the water from operational wind turbine generators. The project design envelope gives turbine sizes of between 9 MW and 20 MW.				

Table 6-1 Summary of the possible noise making activities at EA2 and EA1N other than piling

The NPL Good Practice Guide 133 for underwater noise (Robinson *et al.* 2014) indicates that under certain circumstances, a simple modelling approach may be considered acceptable. Such an approach has been used for these sources, which are variously either comparatively quiet (e.g. drilling and cable laying) or if detailed modelling would imply an unwarranted accuracy (e.g. where data is limited such as with turbine operational noise and UXO detonations). The high-level overview of modelling that has been presented is considered sufficient and there would be little benefit in using a more detailed model at this stage. The limitations of this approach are noted, including the lack of frequency or bathymetry dependence.

6.2 UXO detonation

A number of UXO devices with a range of charge weights (or quantity of contained explosive) have been identified within the boundary of the EA2 and EA1N sites. These need to be removed before construction can begin. There are expected be a variety of explosive types, many of which are likely to have been subject to degradation and burying over time. Two otherwise identical explosive devices are likely to produce different blasts in the case where one has spent an extended period on the sea bed. A selection of explosive sizes has been considered based on site surveys and in each case, it has been assumed that the maximum explosive charge in each device is present and detonates with the clearance.

6.2.1 Estimation of underwater noise levels

The noise produced by the detonation of explosives is affected by several different elements, only one of which, the charge weight, can easily be factored into a calculation. In this case the charge weight is based on the equivalent weight of TNT. Many other elements relating to its situation (e.g. its design, composition, age, position, orientation, whether it is covered by sediment) and exactly how they will

affect the sound produced by detonation are usually unknown and cannot be directly considered in this type of assessment. This leads to a high degree of uncertainty in the estimation of the source noise level (i.e. the noise level at the position of the UXO). A worst-case estimation has therefore been used for calculations, assuming the UXO to be detonated is not buried, degraded or subject to any other significant attenuation from its 'as new' condition.

The consequence of this is that the noise levels produced, particularly by the larger explosives under consideration, are likely to be over-estimated as some degree of coverage by sediment and degradation would be expected.

The range of equivalent charge weights of the potential UXO devices that could be present within the EA2 and EA1N site boundaries have been provided as 200, 300, 400, and 700 kg. Estimation of the source noise level for each charge weight has been carried out in accordance with the methodology of Soloway and Dahl (2014), which follows Arons (1954) and MTD (1996).

6.2.2 Estimation of propagation of underwater noise

For this assessment, the attenuation of the noise from UXO detonation has been accounted for in calculations using geometric spreading and a sound absorption coefficient, primarily using the methodologies cited in Soloway and Dahl (2014), which establishes a trend based on measured data in open water given by, for SPL:

$$SPL_{peak} = 52.4 \times 10^6 \left(\frac{R}{W^{1/3}}\right)^{-1.13}$$

and for SEL:

$$SEL = 6.14 \times \log_{10} \left(W^{1/3} \left(\frac{R}{W^{1/3}} \right)^{-2.12} \right) + 219$$

These equations give a relatively simple calculation which has been used to give an indication of the range of effect. The equation does not take into account variable bathymetry or seabed type, and thus calculation results will be the same regardless where it is used. An attenuation correction has been added to the Soloway and Dahl (2014) equations for the absorption over long ranges (i.e. of the order of thousands of metres), based on measurements of high intensity noise propagation taken in the North and Irish Seas in similar depths to that present at EA2 and EA1N.

Despite this attenuation correction, the resulting noise levels still need to be considered carefully. For example, SPL_{peak} noise levels over larger distances are difficult to predict accurately (von Benda-Beckmann *et al.*, 2015). Soloway and Dahl (2014) only verify results from the equation above for small charges and at ranges of less than 1 km, although the results do agree with the measurements presented by von Benda-Beckmann *et al.* (2014). At longer ranges, greater confidence is expected with the calculations using SELs.

A further limitation in the Soloway and Dahl (2014) equation that must be considered are that variation in noise levels at different depths are not taken into account. Where animals are swimming near the surface, the acoustics can cause the noise level, and hence the exposure, to be lower (MTD, 1996). The risk to animals near the surface may therefore be lower than indicated by the impact ranges given and therefore the results presented can be considered conservative in respect of the impact at different depths.

Additionally, an impulsive wave tends to be smoothed (i.e. the pulse becomes longer) over distance (Cudahy and Parvin, 2001), meaning the injurious potential of a wave at greater range can be even lower than just a reduction in the absolute noise level. An assessment in respect of SEL is considered preferential at long range as it takes into account the overall energy and the smoothing of the peak is less critical.

The selection of assessment criteria must also be considered in light of this. The smoothing of the pulse at range means that technically it develops into a 'non-pulse' of the order of 2 km to 5 km. This range is still to be formally determined and will be different depending on the noise source and conditions. This study has presented impact ranges for both non-impulsive and impulsive criteria at greater ranges, and it is suggested that, for any injury ranges calculated using the impulsive criteria in excess of 5 km, the non-pulse criteria should be considered more appropriate. Southall *et al.* (2007) and Lucke *et al.* (2009) are both considered 'impulsive' criteria.

A summary of the unweighted UXO source levels calculated using this method for this modelling are given in Table 6-2.

	200 kg charge weight	300 kg charge weight	500 kg charge weight	700 kg charge weight
SPL _{peak} source level (dB re 1 µPa @ 1 m)	291.7	293.0	294.7	295.8
SEL _{ss} source level (dB re 1 µPa ² s @ 1 m)	233.7	234.8	236.2	237.1

Table 6-2 Summary of the unweighted SPLpeak and SELss source levels used for UXO modelling

6.2.3 Impact ranges

Table 6-3 to Table 6-10 present the impact ranges for UXO detonation, considering various charge weights and impact criteria. It should be noted that Popper *et al.* (2014) gives specific impact criteria for explosions (Table 2-13). Similarly to the impact piling modelling the previous section, all SEL_{cum} criteria assume a fleeing animal using the same assumptions as presented in section 2.2.2 and ranges smaller than 50 m have not been presented.

Although the impact ranges presented in the following tables are large, the duration the noise is present must be taken into account. For detonation of UXO each explosion is only a single noise event, compared to the multiple pulse nature of impact piling.

	MFS (2018) eighted SPL _{peak}	200 kg charge weight	300 kg charge weight	500 kg charge weight	700 kg charge weight
	219 dB (LF)	219 dB 1.5 km		2.1 km	2.3 km

Popper <i>et al.</i> (2014)	200 kg	300 kg	500 kg	700 kg
Unweighted SPL _{peak}	charge weight	charge weight	charge weight	charge weight
234 dB (Mortality and potential mortal injury)	350 m	400 m	470 m	530 m
229 dB (Mortality and potential mortal injury)	580 m	660 m	790 m	880 m

Table 6-10 Summary of the impact ranges for UXO detonation using the unweighted SPL_{peak}, explosion noise criteria from Popper et al. (2014) for marine mammals at EA2 and EA1N

It can be seen that the ranges of impact for PTS to LF and HF cetaceans using impulse-type criteria are in excess of 5 km. However, using the non-pulse criteria, the impact range all species for PTS criteria are less than 1 km. It is suggested that 5 km is likely to be the limit of risk of PTS onset.

6.3 Other construction activities

For the purposes of identifying the greatest noise impacts, approximate subsea noise levels have been predicted using a simple modelling approach based on measured data scaled to relevant parameters for the site and specific noise source. Predicted source levels at 1 m range for the construction activities are presented in Table 6-11. As previously, all SEL_{cum} criteria use the same assumptions as presented in section 2.2.2, and ranges smaller than 50 m (single strike) and 100 m (cumulative) have not been presented. Operational WTGs have been assessed separately in section 6.4.

At the modelled noise levels, any marine mammal would have to remain in close proximity (in most cases less than 50 m) from the source continuously for 24 hours to be exposed to levels sufficient to induce PTS as per NMFS (2018). In most hearing groups, the noise levels are low enough that there is negligible risk. There is a low to negligible risk of any injury or TTS to fish, in line with guidance for continuous noise sources in Popper *et al.* (2014). All sources presented here much quieter than those presented for impact piling in section 5.

These results are summarised in Table 6-12 to Table 6-15. It is worth noting that NMFS (2018), Southall *et al.* (2007) and Popper *et al.* (2014) give different criteria for non-impulsive or continuous noise sources (see section 2.2.2) and the discussion in section 6.2.2; all sources in this section are considered non-pulse or continuous-type.

	Estimated unweighted source level	Comments
Dredging	186 dB re 1 μPa @ 1 m (RMS)	Based on five datasets from suction and cutter suction dredgers.
Drilling	179 dB re 1 μPa @ 1 m (RMS)	Based on seven datasets of offshore drilling using a variety of drill sizes and powers.
Cable laying	171 dB re 1 μPa @ 1 m (RMS)	Based on eleven datasets from a pipe laying vessel measuring 300 m in length; this is considered a worst-case noise source for cable laying operations.
Rock placement	172 dB re 1 μPa @ 1 m (RMS)	Based on four datasets from rock placement vessel 'Rollingstone.'
Trenching	172 dB re 1 μPa @ 1 m (RMS)	Based on three datasets of measurements from trenching vessels more than 100 m in length.
Vessel noise (large)	171 dB re 1 μPa @ 1 m (RMS)	Based on five datasets of large vessels including container ships, FPSOs and other vessels more than 100 m in length. Vessel speed assumed as 12 knots.
Vessel noise (medium)	164 dB re 1 μPa @ 1 m (RMS)	Based on three datasets of moderate sized vessels less than 100 m in length. Vessel speed assumed as 12 knots.

Table 6-11 Summary of the estimated unweighted source levels for the different construction noise sources considered

6.4 Operational WTG noise

It is believed that the main source of underwater noise from operational turbines will be mechanically generated vibration from the rotating machinery in the turbines, which is transmitted into the sea through the structure of the pile and foundations (Nedwell *et al.*, 2003a). Noise levels generated above the water surface are low enough that no significant airborne sound will pass from the air to the water.

The project design envelope for EA2 and EA1N gives the maximum potential WTG output as 19 MW. A summary of operational WTG where measurements have been collected is given in Table 6-16.

	Lynn	Inner Dowsing	Gunfleet Sands 1 & 2	Gunfleet Sands 3
Type of turbine	Siemens SWT-	Siemens SWT-	Siemens SWT-	Siemens SWT-
used	3.6-107	3.6-107	3.6-107	6.0-120

Table 6-16 Characteristics of measured operational wind farms used as a basis for modelling

The estimation of the effects of operational noise in these situations has two features that make it harder to assess compared with noise sources such as impact piling. Primarily, the problem is one of level; noise measurements made at many wind farms have demonstrated that the operational noise produced was at such a low level that it was difficult to measure relative to the background noise (Cheesman, 2016). Also, an offshore wind farm should be considered as an extended, distributed noise source, as opposed to a 'point source' as would be appropriate for pile driving at a single location, for example. The measurement techniques used at the sites above have dealt with these issues by considering the operational noise spectra in terms of levels within and on the edge of the wind farm (but relatively close to the turbines, so that some noise above background could be detected).

The considered turbine size for modelling at this wind farm is larger than those for which data is available. EA2 and EA1N are also in greater water depths, and as such, estimations of a scaling factor must be conservative to minimise the risk of underestimating the noise. However, it is recognised that the available data on which to base the scaling factor is limited and the extrapolation that must be made is significant.

The operational source levels (as SPL_{RMS}) for the measured sites are given in Table 6-17 (Cheesman, 2016), with an estimated source level for EA2 and EA1N in the bottom row. To predict operational WTG noise levels at EA2 and EA1N, the level sampled at each of the sites have been taken and then a linear correction factor has been included to scale up the source levels (see Figure 6-1). A linear fit was applied to the data available for operational wind turbine noise as this was the extrapolation that would lead to the highest, and thus worst case, estimation of source noise level from the larger 19 MW turbine. This resulted in an estimated source level of 164 dB SPL_{RMS}, 18 dB higher than the 6 MW turbine, the largest for which noise data is available. Alternative calculation methods were considered but rejected as they led to a lower source level. Using a logarithmic fit (3 dB per doubling of power output) to data would lead to a source level of 151 dB SPL_{RMS}. A larger 6 dB increase per doubling of power output would lead to a source level of 156 dB SPL_{RMS}.

A summary of the predicted impact ranges is given in Table 6-18 to Table 6-21. All SEL_{cum} criteria use the same assumptions as presented in section 2.2.2, ranges smaller than 50 m (single strike) and 100 m

(cumulative) have not been presented, and NMFS (2018), Southall et al. (2007) and Popper et al. (2014) give different criteria for non-impulsive or continuous noise sources.

	Unweighted source level (RMS)
Lynn	141 dB re 1 μPa (RMS) @ 1 m
Inner Dowsing	142 dB re 1 μPa (RMS) @ 1 m
Gunfleet Sands 1 & 2	145 dB re 1 μPa (RMS) @ 1 m
Gunfleet Sands 3	146 dB re 1 μPa (RMS) @ 1 m
EA2/EA1N (19 MW)	164.1 dB re 1 µPa (RMS) @ 1 m

Lucke et al. (2009)	Operational WTG (19 MW)
179 dB Unwtd SELss (PTS)	< 50 m
164 dB Unwtd SELss (TTS)	< 50 m
145 dB Unwtd SELss (Behavioural)	80 m

Table 6-20 Summary of the harbour porpoise impact ranges from Lucke et al (2009) for operational WTGs at EA2 and EA1N

Popper <i>et al.</i> (2014)	Operational WTG (19 MW)
170 dB Unwtd SPL _{RMS} (48h) (Recoverable injury)	< 50 m
158 dB Unwtd SPL _{RMS} (12h) (TTS)	< 50 m

Table 6-21 Summary of the impact ranges for shipping and continuous noise from Popper et al (2014) for operational WTGs for species of fish (swim bladder involved in hearing) at EA2 and EA1N

These results show that, for operational WTGs, any injury risk is minimal, even assuming the receptor (marine mammal or fish) stays close to the turbine for 24 hours. Taking both sets of results into account (operational WTG noise and noise sources related to construction in section 6.3) and comparing them to the impact piling source levels in the previous section (specifically section 5.2), it is clear that noise from impact piling results in much greater levels and hence should be considered the activity which has the potential to have the greatest effect during the OWF development.

7 Summary and conclusions

Subacoustech Environmental has undertaken a study on behalf of Royal HaskoningDHV to assess the effect of underwater noise during the development of the EA2 and EA1N Offshore Wind Farms. The study primarily focused on impact piling noise as this is the foundation installation method known to have the greatest potential underwater noise impacts.

The level of underwater noise from the installation of monopiles and pin piles during construction has been estimated by using the INSPIRE subsea noise modelling software, which considers a wide variety of input parameters including bathymetry, hammer blow energy and frequency content of the noise.

Two representative locations were chosen at each of the sites to give spatial variation as well as changes in depth. At each location, monopiles installed with a maximum hammer blow energy of 4000 kJ and pin piles installed with a maximum hammer blow energy of 2400 kJ were modelled. The results showed that greater levels of noise are predicted along transects travelling through deeper water.

The modelling results were analysed in terms of relevant noise metrics to assess the impacts of the predicted impact piling noise on marine mammals and fish.

NMFS (2018), Southall *et al.* (2007) and Lucke *et al.* (2009) all give impact criteria for various species of marine mammals using single pulse and cumulative metrics, both weighted (to account for the hearing sensitivity of the species under consideration) and unweighted. The largest impact ranges for these criteria are summarised in Table 7-1. For all cases in the table below, the worst-case location at EA1N has been used as this provided most of the largest impact ranges.

Criteria	Effect	Species	Monopile (4000 kJ)	Pin Pile (2400 kJ)
		LF Cetacean	17 km	21 km
	PTS	MF Cetacean	< 100 m	< 100 m
	(Weighted SELcum)	HF Cetacean	6.6 km	21 km
NMFS (2018)		PW Pinniped	5.2 km	7.1 km
NIVIFS (2016)		LF Cetacean	40 km	45 km
	TTS	MF Cetacean	< 100 m	5.8 km
	(Weighted SELcum)	HF Cetacean	27 km	45 km
		PW Pinniped	25 km	28 km
	PTS (M-Weighted SELcum)	LF Cetacean	4.4 km	5.7 km
		MF Cetacean	3.0 km	5.8 km
		HF Cetacean	1.8 km	3.8 km
		PW Pinniped	22 km	26 km
Southall <i>et al</i> .	TTS	LF Cetacean	2.1 km	1.9 km
(2007)		MF Cetacean	580 m	710 m
	(M-Weighted SELss)	HF Cetacean	440 m	490 m
		PW Pinniped	6.6 km	7.5 km
		LF Cetacean	35 – 51 km	34 – 51 km
	Behavioural (SELss)	MF Cetacean	11 – 23 km	11 – 22 km
Lucke et al.	Auditory injury (SELss)	Harbour	3.7 km	3.5 km
	TTS (SELss)	porpoise	3.4 km	18 km
(2009)	(2009) Behavioural (SELss)		3.6 km	46 km

Table 7-1 Summary of the maximum predicted impact range for marine mammal criteria (EA1N, worst-case location)

Popper *et al.* (2014) gives impact range criteria for various groups of fish, with ranges of up to 500 m for recoverable injury (SPL_{peak}) and out to 29 km for TTS (SEL_{cum}) at the maximum blow energies, when considering monopiles at the worst-case modelling location at EA1N. For all SEL_{cum} criteria, greater impact ranges were calculated for pin piles compared to monopiles due to the faster strike rate assumed for those scenarios.

Further impact piling modelling was carried out to demonstrate the reductions in noise levels and impact ranges relating to only reaching 75% or 50% of the maximum blow energy compared to reaching 100%, these results are presented in Appendix A.

Noise sources other than piling have been considered using a high-level, simple noise modelling approaches, including UXO detonation, dredging, drilling, cable laying, rock placement, trenching, vessel noise and noise from operational wind turbines. For UXO detonation, there is a risk of PTS up to 11 km for the largest UXO considered, a 700 kg device using the impulsive NMFS criteria, for HF cetaceans. However, it has been suggested that at distances beyond five kilometres the smoothing of the noise pulse means that the 'non-pulse' criteria may be more appropriate; in this case the risk of PTS to any species reduces to less than one kilometre and thus the range of risk of PTS during UXO detonation is likely to be 5 km.

The predicted noise levels for the other construction noise sources and during turbine operation are well below those predicted for impact piling noise. The risk of any potential injurious effects to fish or marine mammals from these sources are expected to be negligible as the noise emissions from these are very close to, or below, the appropriate injury criteria at the source of the noise.

Appendix A Additional impact piling modelling results (75% and 50% maximum blow energy)

A.1 Modelling parameters

An impact piling driveability study has not yet been completed, and as such additional modelling runs have been undertaken to assess noise levels assuming the blow energy only reaches 75% or 50% of the maximum hammer blow energy during the main piling. In each case the soft start remains 10% of the maximum hammer energy and the total number of strikes and strike rate remain the same as the 100% hammer blow energy scenarios for these modelling runs. The same modelling locations have also been used.

Table A-1 to Table A-4 summarise the ramp up scenarios used for these additional modelling runs and Table A-5 and Table A-6 present the single strike source levels used for the modelling. The results are presented in the following sections and compared with the 100% hammer blow energy scenarios in section A.4.

	Soft start (10%)	Ramp up	Main piling (75%)
Monopile blow energy	400 kJ	Gradual increase	3000 kJ
Number of strikes	150 strikes	300 strikes	8850 strikes
Duration	10 minutes	20 minutes	295 minutes
Strike rate	15 strikes per minute		30 strikes per minute

Table A-1 Summary of the ramp up scenario used for calculating cumulative SELs for monopiles up to 75% maximum hammer blow energy

	Soft start (10%)	Ramp up	Main piling (75%)
Pin pile blow energy	240 kJ	Gradual increase	1800 kJ
Number of strikes	150 strikes	300 strikes	6760 strikes
Duration	10 minutes	20 minutes	169 minutes
Strike rate	15 strikes per minute		40 strikes per minute

Table A-2 Summary of the ramp up scenario used for calculating cumulative SELs for a single pin pile up to 75% maximum hammer blow energy

	Soft start (10%)	Ramp up	Main piling (50%)
Monopile blow energy	400 kJ	Gradual increase	2000 kJ
Number of strikes	150 strikes	300 strikes	8850 strikes
Duration	10 minutes	20 minutes	295 minutes
Strike rate	15 strikes per minute		30 strikes per minute

Table A-3 Summary of the ramp up scenario used for calculating cumulative SELs for monopiles up to 50% maximum hammer blow energy

	Soft start (10%)	Ramp up	Main piling (50%)
Pin pile blow energy	240 kJ	Gradual increase	1200 kJ
Number of strikes	150 strikes	300 strikes	6760 strikes
Duration	10 minutes	20 minutes	169 minutes
Strike rate	15 strikes per minute		40 strikes per minute

Table A-4 Summary of the ramp up scenario used for calculating cumulative SELs for a single pin pile up to 50% maximum hammer blow energy

		SPL _{peak} source level	SEL _{ss} source level
Monopile	50% (2000kJ)	239.1 dB re 1 μPa @ 1 m	222.7 dB re 1 µPa ² s @ 1 m
Monophe	75% (3000kJ)	239.4 dB re 1 µPa @ 1 m	223.1 dB re 1 µPa ² s @ 1 m

Table A-5 Summary of the unweighted single strike source levels used for modelling monopiles in this study

		SPL _{peak} source level	SEL _{ss} source level
Pin pile	50% (1200kJ)	238.4 dB re 1 μPa @ 1 m	222.0 dB re 1 µPa ² s @ 1 m
Fill plie	75% (1800kJ)	238.9 dB re 1 uPa @ 1 m	222.3 dB re 1 uPa ² s @ 1 m

Table A-6 Summary of the unweighted single strike source levels used for modelling pin piles in this study

A.2 75% maximum blow energy modelling results

The following sections present the impact ranges using the various noise metrics and criteria for reaching 75% of the maximum hammer blow energy. This modelling uses the parameters detailed in Table A-1, Table A-2 and Table A-5.

Table A-78 Summary of the unweighted single strike and cumulative impact ranges for fish (swim bladder involved in hearing) using the impact piling criteria from Popper et al. (2014) for installation of a pin pile at EA1N using the 50% maximum hammer blow energy of 1200 kJ

A.4 Summary

The previous sections present impact ranges for scenarios where the blow energy only reaches 75% and 50% of the maximum hammer blow energy during the main piling. Table A-79, below, gives a brief summary of the reductions in impact ranges for TTS in LF cetaceans (NMFS, 2018) for the worst-case location at EA1N; one of the criteria with the largest expected impact ranges. The results show that the reduction in impact range is only minor when these lower hammer blow energies are reached instead of the maximum hammer blow energy.

Effect	Maximum blow energy	Monopile (4000 kJ)	Pin Pile (2400 kJ)
LF Cetacean TTS	100%	40 km	45 km
(Weighted SELcum)	75%	40 km	44 km
(NMFS, 2018)	50%	39 km	43 km

Table A-79 Summary of the LF cetacean TTS impact ranges showing the reductions in SEL_{cum} impact ranges when reducing the maximum hammer blow energy (EA1N, worst-case location).
